We consider a threshold-crossing spiking process as a simple model for the activity within a population of neurons. Assuming that these neurons are driven by a common fluctuating input with gaussian statistics, we evaluate the cross-correlation of spike trains in pairs of model neurons with different thresholds. This correlation function tends to be asymmetric in time, indicating a preference for the neuron with the lower threshold to fire before the one with the higher threshold, even if their inputs are identical. The relationship between these results and spike statistics in other models of neural activity is explored. In particular, we compare our model with an integrate-and-fire model in which the membrane voltage resets following each spike. The qualitative properties of spike cross-correlations, emerging from the threshold-crossing model, are similar to those of bursting events in the integrate-and-fire model. This is particularly true for generalized integrate-and-fire models in which spikes tend to occur in bursts, as observed, for example, in retinal ganglion cells driven by a rapidly fluctuating visual stimulus. The threshold-crossing model thus provides a simple, analytically tractable description of event onsets in these neurons.

1 Introduction ---

Probing the relationship between a stimulus and the spike train, generated by a population of neurons, is a central theme in the study of neural activity (Rieke, Warland, de Ruyter van Steveninck, & Bialek, 1996). Correlations

in the spike timing of different neurons are of interest in this context for two main reasons. First, spike correlations are informative about the structure of the neural code, beyond what could be inferred from the firing properties of single neurons alone. Second, correlations are often thought to reflect the structural properties of the neural network (Ginzburg & Sompolinsky, 1994).

Correlated firing in a pair of neurons can arise because of two distinct reasons: the existence of a connection between the neurons (direct or indirect) and the existence of a common input to the two neurons that is varying in time. Here we focus on the second possible source for correlated activity. We consider model neurons that receive an analog, continuous stimulus and respond to it by generating a discrete sequence of spiking events. The main question that we address is how the statistical properties of the fluctuating stimulus affect the structure of spike correlation functions.

Correlated inputs to neurons were considered theoretically mainly in the context of their effect on single-neuron properties, such as firing rate (Tuckwell, 1988b; Salinas & Sejnowski, 2000; Moreno, de la Rocha, Renart, & Parga, 2002; Kuhn, Aertsen, & Rotter, 2003), coefficient of variation (CV) (Tuckwell, 1988b; Brunel & Sergi, 1998; Salinas & Sejnowski, 2000, 2002; Stroeve & Gielen, 2001; Schwalger & Schimansky-Geier, 2008), and spike-triggered average stimulus (Kanev, Wenning, & Obermayer, 2003; Badel, Gerstner, & Richardson, 2006; Paninski, 2006). These works considered integrate-and-fire model neurons (Tuckwell, 1988a; Gerstner & Kistler, 2002).

The nonleaky integrate-and-fire model is relatively tractable analytically (Tuckwell, 1988b; Paninski, 2006). In comparison, analytical treatment of the leaky integrate-and-fire (LIF) neuron is considerably more difficult (Burkitt, 2006). Some analytical results are available for the firing rate (Salinas & Sejnowski, 2000; Moreno et al., 2002; Kuhn et al., 2003), whereas analytical results for the ISI and the CV are available only in particular limits such as slowly varying (Moreno-Bote & Parga, 2006; Schwalger & Schimansky-Geier, 2008) or binary (Salinas & Sejnowski, 2002) inputs. Other results were obtained for the LIF model from computer simulations (Salinas & Sejnowski, 2000; Stroeve & Gielen, 2001). In particular, Stroeve and Gielen (2001) included a simulation study of correlations in spiking of LIF neurons that receive partly overlapping input. Correlations due to partly overlapping input were also studied analytically, but only in the limit where the input is slowly fluctuating in time (Moreno-Bote & Parga, 2006).

Here we consider a simpler model of neural response, where neurons spike whenever a generating potential $g(t)$, linearly related to the neuron's stimulus, crosses a threshold in its rising phase. For sufficiently simple stimuli, this model is analytically tractable, which allows spike correlation functions to be evaluated in closed form.

Threshold-crossing processes without a reset were previously analyzed as models for neural firing. The spike autocorrelation function of a neuron

was considered by Jung (1994), while making specific assumptions on the nature of the fluctuating potential. Here we evaluate the auto- and cross-correlation in spike timing of neurons with different thresholds, while making fewer assumptions on the generating potentials eliciting the spikes. These are assumed to be gaussian and may be identical or partially overlapping in different neurons.

As in the case of linear-nonlinear (LN) models (Korenberg & Hunter, 1986; Chichilnisky, 2001), we assume that a neuron responds to a temporal convolution of its stimulus with a linear kernel. However, in the LN model, spiking is stochastic, whereas in the threshold-crossing model, the spike timing is precisely determined by the stimulus. This aspect of the model is motivated by the observation, in various neural assays, of responses that are precisely repeatable across multiple trials (Mainen & Sejnowski, 1995; Berry, Warland, & Meister, 1997; de Ruyter van Steveninck, Lewen, Strong, Koberle, & Bialek, 1997; Meister & Berry, 1999; Keat, Reinagel, Reid, & Meister, 2001; Uzzell & Chichilnisky, 2004), much more than can be described by Poisson statistics, particularly when the stimulus is strongly fluctuating in time.

The model and our main assumptions are presented in section 2. Before discussing spike correlation functions, we first evaluate the firing rate in section 3, and then the spike-triggered average stimulus and covariance in section 4. We evaluate spike auto- and cross-correlation functions in section 5. These results are compared with computer simulations of model neurons that spike according to several variations of the leaky integrate-and-fire model (see section 6).

2 Formalism and Assumptions

We consider one or more neurons that respond to the same generating potential g and elicit a spike whenever g crosses a threshold in its rising phase. The spike train generated by the neuron i can be written as

$$\chi_i(t) = \delta [g(t) - \theta_i] \dot{g}(t) \Theta [\dot{g}(t)], \quad (2.1)$$

where g is the generating potential. The Heaviside step function $\Theta [\dot{g}(t)]$ restricts the firing to the upward crossing events.

We assume that g is stationary and gaussian and has zero mean. The generating potential is thus fully characterized by its correlation function,

$$\langle g(t)g(t') \rangle = w(|t' - t|), \quad (2.2)$$

where the angled brackets stand for an ensemble average over all possible realizations of the fluctuating generating potential g . Later in section 5, we consider a more general situation of a population of neurons, whose

generating potentials g_i are jointly gaussian, characterized by their covariance functions

$$\langle g_i(t)g_j(t') \rangle = w_{ij}(t' - t). \quad (2.3)$$

The properties of a model neuron, responding to a stimulus whose mean differs from zero, can be obtained from the zero-mean case simply by adjusting the threshold.

For a single neuron, the behavior of $w(\Delta t)$ at small Δt determines the firing rate and the short-time behavior of the spike autocorrelation (see section 5). We assume that an expansion of $w(\Delta t)$ exists around $\Delta t = 0$:

$$w(\Delta t) = W_0 + W_1|\Delta t| + \frac{1}{2}W_2\Delta t^2 + \frac{1}{3!}W_3|\Delta t|^3 + \dots \quad (2.4)$$

We further assume that W_1 vanishes and that W_2 is negative, for reasons that will become clear later on. As seen below, it is necessary to treat different classes of processes separately, depending on which other coefficients in the expansion are nonzero. One important class is the case where $W_3 \neq 0$. This is the typical situation if a causal filter is involved in the generation of $g(t)$. For comparison, we also briefly consider, in section 5, the case where all the coefficients with odd indices vanish—for example, a process with a gaussian correlation function, $w(t) = \sigma^2 \exp(-t^2/2\tau^2)$.

2.1 Relationship Between g and the Stimulus. The generating potential in our model is linearly related to the stimulus s ,

$$g = f \circ s, \quad (2.5)$$

where the symbol \circ stands for convolution. We assume that s is a zero-mean, uncorrelated gaussian process:

$$\langle s(t)s(t') \rangle = \sigma_0^2 \delta(t' - t). \quad (2.6)$$

The correlation function of g is then

$$w(\Delta t) = \sigma_0^2 \int f(t)f(t + \Delta t) dt. \quad (2.7)$$

Note that $W_0 = \sigma_0^2 \int_{-\infty}^{\infty} [f(t)]^2 dt > 0$ and that if f is sufficiently regular, $W_2 = -\sigma_0^2 \int_{-\infty}^{\infty} [f'(t)]^2 dt < 0$.

The assumption that s is uncorrelated is made for simplicity of presentation and because uncorrelated flickering stimuli are often used experimentally. The results below generalize in a straightforward manner also to the case where s is a correlated gaussian process.

2.2 Specific Forms for f and w . In the following sections, we first derive results that are valid generally for any $w(\Delta t)$. We then illustrate these results

with a specific example, where we assume a particular form of f . In these examples, the filter f is a causal filter of the form

$$f(t) = \begin{cases} 0 & t < 0 \\ \frac{e^{-t/\tau_2} - e^{-t/\tau_1}}{\tau_2 - \tau_1} & t > 0 \end{cases}, \quad (2.8)$$

which is a combination of two single-exponential filters with time constants τ_1 and τ_2 . Using equation 2.7,

$$w(\Delta t) = \sigma^2 \frac{\tau_2 \exp(-|\Delta t|/\tau_2) - \tau_1 \exp(-|\Delta t|/\tau_1)}{\tau_2 - \tau_1}, \quad (2.9)$$

where

$$\sigma^2 = \frac{\sigma_0^2}{2(\tau_1 + \tau_2)} \quad (2.10)$$

is the variance of g .

In the particular case where $\tau_1 = \tau_2 \equiv \tau$, f is a so-called alpha filter,

$$f(t) = \begin{cases} 0 & t < 0 \\ \frac{t}{\tau^2} e^{-t/\tau} & t > 0 \end{cases} \quad (2.11)$$

and

$$w(\Delta t) = \frac{\sigma^2}{\tau} (|\Delta t| + \tau) e^{-|\Delta t|/\tau}. \quad (2.12)$$

The expansion of $w(\Delta t)$ for small Δt , equation 2.4, yields $W_1 = 0$ and

$$\begin{aligned} W_0 &= \sigma^2, & W_2 &= -\frac{\sigma^2}{\tau_1 \tau_2}, & W_3 &= \frac{\tau_1 + \tau_2}{\tau_1^2 \tau_2^2} \sigma^2, \\ W_4 &= -\frac{\tau_1^2 + \tau_1 \tau_2 + \tau_2^2}{\tau_1^3 \tau_2^3} \sigma^2, \dots \end{aligned} \quad (2.13)$$

3 Firing Rate

We begin with the relatively simple problem of evaluating the firing rate of a single neuron (Rice, 1954),

$$r = \langle \chi(t) \rangle, \quad (3.1)$$

where χ is given by equation 2.1. Although this quantity has been calculated before, we derive it here in some detail, because the derivation

generalizes to the higher-order moments that are calculated later (whose detailed derivation is presented in the appendixes.) The firing rate r can be written as

$$r = \int_0^\infty dq q \cdot p(\theta, q), \quad (3.2)$$

where $p(g, q)$ is the joint probability distribution for the generating potential to be equal to g and for its derivative, at the same time, to be equal to q . To evaluate this and similar quantities, we use an identity that holds for a general gaussian signal $g(t)$ with correlation function $w(\Delta t)$: if ζ_1, \dots, ζ_n are all scalar random variables that depend linearly on the process g ,

$$\zeta_i = \int dt \alpha_i(t) g(t), \quad (3.3)$$

then the joint probability distribution of ζ_1, \dots, ζ_n is equal to

$$p(\zeta_1, \dots, \zeta_n) = \frac{1}{Z} \exp \left[-\frac{1}{2} \boldsymbol{\zeta}^T A^{-1} \boldsymbol{\zeta} \right], \quad (3.4)$$

where $Z = [(2\pi)^n \det A]^{1/2}$ and

$$A_{ij} = \int dt \int dt' \alpha_i(t) w(t' - t) \alpha_j(t'). \quad (3.5)$$

The generating potential and its derivative at time $t = 0$ correspond to $\zeta_1 = g(0)$ and $\zeta_2 = \dot{g}(0)$; therefore, $\alpha_1 = \delta(t)$ and $\alpha_2 = -\dot{\delta}(t)$, so that

$$A = \begin{bmatrix} W_0 & 0 \\ 0 & -W_2 \end{bmatrix}. \quad (3.6)$$

The off-diagonal terms are proportional to $w'(0)$, which vanishes if $W_1 = 0$, as we assumed.¹ We thus have

$$p(g, q) = \frac{1}{Z} \exp \left(-\frac{g^2}{2W_0} - \frac{q^2}{-2W_2} \right), \quad (3.7)$$

¹If $W_1 \neq 0$, $w(\Delta t)$ does not have a derivative at $\Delta t = 0$, and the derivation performed here fails. A typical example is given by uncorrelated noise passed through a single-exponential filter. For this process, the firing rate diverges (see below).

and the integral 3.2 yields

$$r = \frac{1}{2\pi} \left[\frac{-W_2}{W_0} \right]^{1/2} \exp\left(-\frac{\theta^2}{2W_0}\right). \quad (3.8)$$

Hence, W_2 must be negative for the firing rate to be finite.

For the generating potential of equations 2.8 and 2.9,

$$r = \frac{1}{2\pi (\tau_1 \tau_2)^{1/2}} \exp\left(-\frac{\theta^2}{2\sigma^2}\right). \quad (3.9)$$

If either τ_1 or τ_2 vanishes, the firing rate diverges. Hence, a generating potential obtained by convolving uncorrelated noise with a single exponential filter has an infinite rate of threshold crossings. In such a process, there are finite intervals in which the number of crossings is infinite and others in which no firing occurs.²

4 Spike-Triggered Average Stimulus

The spike-triggered averaged stimulus (STA) is the mean stimulus given that a spike was generated at a particular time. Because the input is assumed to be stationary, the STA is only a function of the time difference relative to the spike time,

$$f_{\text{STA}}(\Delta t) = \frac{1}{r} (s(\Delta t) \cdot \chi(0)), \quad (4.1)$$

where r is the firing rate, χ is determined by g , as in equation 2.1, and the spike time was arbitrarily chosen to be zero. If one assumes that spiking is described by an LN model with filter f and if the stimulus is uncorrelated gaussian noise, $f_{\text{STA}}(\Delta t)$ is proportional to $f(-\Delta t)$ (Chichilnisky, 2001; Paninski, 2003). Hence, it is common to probe the spatiotemporal filter applied by a neuron on its stimulus by measuring f_{STA} (Schwartz, 2006), in particular, in the visual sensory system (Rieke, 2001; Chichilnisky & Kalmar, 2002; Baccus & Meister, 2002; Rust, Schwartz, Movshon, & Simoncelli, 2005; Hosoya, Baccus, & Meister, 2005).

To compute f_{STA} for a threshold-crossing spiking neuron, we need the joint probability distribution function $p(g_1, q_1; s_2)$ for $g(0) = g_1$, $\dot{g}(0) = q_1$, and $s(\Delta t) = s_2$, evaluated in appendix A. The STA is then given by

$$f_{\text{STA}}(\Delta t) = \frac{\theta}{A} f(-\Delta t) + \sigma_0 \sqrt{\frac{\pi}{2B}} f'(-\Delta t), \quad (4.2)$$

where $A = W_0/\sigma_0^2 = \int_{-\infty}^{\infty} f^2(t) dt$ and $B = -W_2/\sigma_0^2 = \int_{-\infty}^{\infty} f^2(t) dt$.

²This is related to the short-time properties of the spike autocorrelation function (see section 5) in the limit where τ_1 or $\tau_2 \rightarrow 0$.

The first term in equation 4.2 is proportional to the expectation for the STA in a rate-based linear-nonlinear model (Chichilnisky, 2001). However, for a threshold-crossing spiking neuron, it correctly describes the STA only in the limit of large θ : in contrast, when $\theta = 0$, the STA is proportional to $f'(\Delta t)$.

The result that f_{STA} is a linear combination of the filter and its derivative has a simple geometric interpretation, which is most easily seen by thinking of the stimulus history as an n -dimensional discrete vector. The condition for spiking at time $t = 0$ involves g and its derivative, which are the inner products of the stimulus history with two vectors, f and f' . Because s is uncorrelated, its history vector is distributed in a radially symmetric manner in n -dimensional space. The STA must lie in the two-dimensional subspace spanned by the vectors f and f' .

This result is illustrated in Figure 1a for the generating potential of equations 2.11 and 2.12. With the threshold varying from 0 to 2.5σ , the shape of f_{STA} varies significantly. The dotted lines in the figure (overlapping with the solid line) were obtained from a discrete simulation, using a time step $dt = \tau/100$ and averaging over a simulation run $T/\tau = 10^6$ for $\theta = 0$ and $\theta = 1$, and $T/\tau = 10^8$ for $\theta = 2.5$.

It is interesting to compare these results with what is expected from a leaky integrate-and-fire model neuron (Tuckwell, 1988a; Gerstner & Kistler, 2002). For this case there is no known analytic form for the STA (see, however, Kanev et al., 2003; Badel et al., 2006; Paninski, 2006), but we can evaluate the STA numerically. We assume that the membrane potential of the model neuron is related to the input current via

$$\tau_1 \frac{du}{dt} = -u + I, \quad (4.3)$$

with a reset of the membrane potential to u_r whenever u reaches the threshold θ , whereas the input current is related to the stimulus s by

$$\tau_2 \frac{dI}{dt} = -I + s. \quad (4.4)$$

The subthreshold dynamics of u depends on the stimulus in the same way as the generating potential g depends on stimulus in the threshold-crossing model. The difference between the two models lies in the existence of a reset. For simplicity, we set $u_r = 0$ and $\tau_1 = \tau_2$ for the rest of this section (see also section 6 and appendix D).

Figure 1b shows a comparison between f_{STA} in the integrate-and-fire model (simulation, dotted line: $dt/\tau = 0.01$ and $T/\tau = 10^6$) and f_{STA} in the threshold-crossing spiking model (equation 4.2, solid line). The parameters are as in Figure 1a, with a threshold $\theta = 2.5\sigma$. The two models agree very

Figure 1: (a) STA of a model neuron spiking in response to upward threshold crossing of the generating potential described by equations 2.5, 2.11, and 2.12. The STA, equation 4.2, is plotted for three values of the threshold: $\theta = 2.5\sigma$, σ , and 0, where σ is the standard deviation of $g(t)$ (solid line: analytic expression, dotted lines: simulation). (b) A comparison of the STA for $\theta = 2.5\sigma$ (solid line) with simulation results from a leaky integrate-and-fire neuron with time constants $\tau_1 = \tau_2 = \tau$ and the same threshold, receiving s as its input, and resetting its membrane potential to 0 after each spike (dotted line). The dashed line shows the first term only of equation 4.2. (c) A similar comparison as in *b*, with $\theta = 0.25\sigma$ (solid line, threshold-crossing model; dashed line, leaky integrate-and-fire model).

well in their prediction and differ significantly from that of an LN model, where $f_{\text{STA}}(\Delta t) \propto f(-\Delta t)$ (dashed line).

For a lower threshold, $\theta = 0.25$, the threshold-crossing spiking model and the integrate-and-fire model no longer yield similar predictions for f_{STA} (solid and dashed lines, in Figure 1c). The difference between the cases of high and low threshold is possibly related to the typical interspike interval, which, in the case of a high threshold, is longer, allowing the input to decorrelate between subsequent spikes. The statistics of the input before a spike are thus less influenced, in the case of high threshold, by whether a reset has occurred following the previous spike.

Finally, we note that the threshold-crossing model is similar to a two-dimensional LN model involving two filters, equal to $f(-t)$ and $f'(-t)$. In the analogous LN model, the nonlinear transfer function must be chosen to be narrowly peaked at values of the generating potential close to the threshold, and an appropriate dependence on the derivative must be included as well.³ The result that the STA is a linear combination of the filter f and its derivative thus agrees with the general property of multidimensional LN models, that the STA lies within the subspace spanned by the linear kernels determining the spiking rate (Paninski, 2003; Schwartz, 2006). Similarly, we may expect the spike-triggered covariance (de Ruyter van Steveninck & Bialek, 1988; Schwartz, 2006) to reveal the linear filter f and its derivative f' as spanning this subspace. This is indeed the case (see appendix A).

5 Spike Correlations

We next consider correlations in the spike timing of two neurons, assuming that they receive identical inputs but possibly differ in their thresholds $\theta_{1,2}$. Because the generating potential is assumed to be stationary, the spike correlation function depends on only the time difference between spikes:

$$c(\Delta t) = \langle \chi_1(0) \cdot \chi_2(\Delta t) \rangle. \quad (5.1)$$

From the definition of $\chi_{1,2}$, equation 2.1, the quantity inside the brackets depends on the generating potential and its derivative at $t = 0$ and at $t = \Delta t$.

The detailed form of $c(\Delta t)$ is derived in appendix B, and here we present the main results. The spike correlation function can be written as

$$c(\Delta t) = p(\theta_1; \theta_2) \cdot \int_0^\infty dq_1 \int_0^\infty dq_2 q_1 \cdot q_2 \times \frac{(\det m^{-1})^{1/2}}{2\pi} \exp \left[-\frac{1}{2} (\mathbf{q} - \mathbf{q}_0)^T m^{-1} (\mathbf{q} - \mathbf{q}_0) \right], \quad (5.2)$$

³There is a difference between the two models, however, in that the two-dimensional LN model produces a variable number of spikes within the narrow spiking event.

where $p(\theta_1; \theta_2)$ is the joint probability distribution for $g(0) = \theta_1$ and $g(\Delta t) = \theta_2$ (see equation B.16) and $\mathbf{q}^T = (q_1, q_2)$. The quantity in the second line of the equation is the conditional probability distribution function for $g'(0) = q_1$ and $g'(\Delta t) = q_2$, given that $g(0) = \theta_1$ and $g(\Delta t) = \theta_2$. This conditional distribution is gaussian and is characterized by its mean \mathbf{q}_0 and the covariance matrix m , whose values are derived in the appendix (see equations B.14 and B.15).

5.1 The Spike Autocorrelation Function. We briefly discuss the spike autocorrelation function, corresponding to the case $\theta_1 = \theta_2 \equiv \theta$, and focusing on the behavior at small Δt . Because the spike train $\chi(t)$ is a point process, its autocorrelation function necessarily includes a contribution

$$c(\Delta t) = r\delta(\Delta t) + \dots \quad (5.3)$$

The discussion here concerns nonzero values of Δt , that is, the occurrence of spikes in addition to the one at $t = 0$. The behavior for small Δt is remarkably different for the two classes of generating-potential statistics discussed in section 2: if $W_3 \neq 0$, as in the example of equation 2.13, the spike autocorrelation function tends to a finite value when $\Delta t \rightarrow 0$:

$$c(\Delta t) \rightarrow \frac{W_3}{4\pi^2(-3W_0W_2)^{1/2}} \exp\left(-\frac{\theta^2}{2W_0}\right). \quad (5.4)$$

It is interesting to look at this quantity divided by r , which represents the firing rate at time $t = \Delta t$ after the occurrence of a spike at $t = 0$:

$$\frac{c(\Delta t)}{r} \rightarrow \frac{W_3}{-2\pi\sqrt{3}W_2}. \quad (5.5)$$

This ratio does not depend on θ . By comparing with r itself, we see that if the threshold is high, the spike-conditioned firing rate is much higher than the average firing rate. In other words, once the neuron has fired, it is likely to fire soon again, compared to its baseline firing rate. When the threshold is zero, the spike-conditioned firing rate can be larger or smaller than r , depending on the expansion coefficients W_2 and W_3 . This result is illustrated in Figure 2a, where w is given by equation 2.12.⁴

We note that when $W_3 \neq 0$ as above, the second derivative of the generating potential is an unbounded random process and the first derivative of g is not smooth. This facilitates the generation of successive spikes at short

⁴Note that the conditional firing rate diverges if $\tau_1 \rightarrow 0$ or if $\tau_2 \rightarrow 0$, which can be seen from equation 2.13. This is consistent with the divergence of the average firing rate in this limit and the existence of finite time intervals in which the number of spikes is infinite.

Figure 2: Spike autocorrelation function, $c(\Delta t)$, divided by the average firing rate r , for three values of the threshold: $\theta = 0, 2\sigma$, and 3σ . The generating potential is described by equations 2.5, 2.11, and 2.12. (b) A similar plot for a generating potential having a Gaussian correlation function, $w(t) = \sigma^2 \exp(-t^2/2\tau^2)$.

intervals, since the derivative of g is required to be positive at the interval's edges and negative somewhere in between.

In contrast, when the first derivative of g is a smooth process, we may expect the occurrence of spikes at vanishingly small intervals to be considerably less likely. Indeed, if $w(\Delta t)$ has no irregularities at $\Delta t = 0$, so that all W_i with odd indices vanish, the occurrence of spikes separated by short intervals is strongly suppressed, $c(\Delta t) \sim (\Delta t)^4$ (see appendix C, equations C.10 and C.13). This is illustrated in Figure 2b for a generating potential with a Gaussian correlation function, $w(\Delta t) = \sigma^2 \exp(-\Delta t^2/2\tau^2)$. Note that W_0 and W_2 are the same in the two parts of Figure 2; consequently, the mean firing rates are identical in these two cases.

5.2 Spike Cross-Correlation. We next consider the spike cross-correlation function of two neurons with different thresholds, firing in response to the same stimulus. We note, first, that unless $\theta_1 = \theta_2$, the correlation function is not symmetric with respect to replacement of Δt by $-\Delta t$ or, equivalently, with respect to exchange of the two neurons ($\theta_1 \leftrightarrow \theta_2$). The generating potential is required to have a positive derivative at $t = 0$ and at $t = \Delta t$, and therefore we may expect a higher probability for joint spiking if the higher of the two thresholds is set at the later time (see Figure 3). This is indeed the case, as demonstrated in Figure 4a for the generating potential described by equation 2.12, and with thresholds set as $\theta_1 = 0.8\sigma$ and $\theta_2 = \sigma$. The preference for one neuron to fire after the other neuron is particularly prominent at short timescales of order τ , but it also has a signature at large timescales (see appendix B).

It is instructive to compare the threshold-crossing model with the prediction of a one-dimensional linear-nonlinear (LN) model (Chichilnisky, 2001). For this comparison, we assume that the linear filter of the LN model

Figure 3: Spike generation events in the threshold-crossing model for two neurons with thresholds θ_1 (thick circle) and $\theta_2 > \theta_1$ (thin circle). In the left plot, neuron 2 fires after neuron 1, whereas in the right plot, neuron 1 fires after neuron 2. In the latter case, the generating potential must reverse the sign of its derivative twice within the time interval separating the two spikes.

is the same as the filter f in the threshold-crossing model and that in both models, the stimulus is uncorrelated gaussian noise. In the LN model, the spike correlation function depends also on the choice of the nonlinear function applied to the outcome of the linear filter. Two particular choices are made in the examples shown in Figure 4b. The first is linear rectification, $\phi(x) \propto \Theta(x - \theta)$ where $\Theta(x) = x$ for $x > 0$ and $\Theta(x) = 0$ for $x < 0$, with thresholds θ_1, θ_2 chosen as in Figure 1a (solid line).

The second example (dashed line) is the case where $\phi(x)$ is nonzero only in a narrow range around θ , $\phi(x) \propto \delta(x - \theta)$. Mathematically, this example compares more directly with the threshold-crossing model, because the LN model produces spikes only at the threshold crossings. The correspondence can be seen in the spike cross-correlation function $c(\Delta t)$ obtained from the LN model in this case, which is calculated in appendix E, equation E.4. In the limit of large Δt , $c(\Delta t)/r_1 r_2 - 1$ in the LN model, equation E.8, is equal to the first term in the large Δt expansion for the threshold-crossing model, equation B.24.

We note two important qualitative differences between the LN model and the threshold-crossing spiking model. First, in the LN model, the spike correlation function is symmetric under time reversal: $c(-\Delta t) = c(\Delta t)$.⁵ A second qualitative difference between the two models, seen in Figure 4, is that the firing of the two neurons is less correlated in the LN model compared to the threshold-crossing spiking model, at short timescales.

5.3 The Limit $\Delta t \rightarrow 0$. In the limit of small Δt , the behavior of $c(\Delta t)$ is substantially different if the neuron with the higher threshold fires before or

⁵This property arises for the following reason. The spike cross-correlation at any two times t_1, t_2 depends on the joint probability distribution of the generating potential values at these times. Assuming that the generating potential is gaussian, this joint distribution function is necessarily symmetric.

Figure 4: (a) The spike correlation function, $c(\Delta t)/r_1 r_2$ (solid line,) of two model neurons with thresholds $\theta_1 = 0.8\sigma$ and $\theta_2 = \sigma$, firing in response to the same stimulus (same as in Figure 2a). The dashed line shows the approximation for small Δt , equations C.2 and C.4 to C.6. At large $|\Delta t|$ the two neurons become decorrelated, and $c(\Delta t)/r_1 r_2$ approaches unity. The inset shows the approximation for weakly correlated neurons, equation B.24 (dashed line), compared with the actual correlation function (solid line). (b) The prediction of a LN model for the spike correlation function, $c(\Delta t)/r_1 r_2$, shown for two different forms of the nonlinearity, as described in the text (linear rectification, solid line; delta function, dashed line).

after the neuron with the lower threshold.⁶ To simplify notation, we assume here that $\theta_2 > \theta_1$.

$\Delta t > 0$: For small Δt , the spike correlation function scales with Δt as

$$c(\Delta t) \sim \frac{(\theta_2 - \theta_1)^2}{\Delta t^3} \exp \left[\frac{1}{2W_2} \left(\frac{\theta_2 - \theta_1}{\Delta t} \right)^2 + \frac{\gamma_1}{\Delta t} \right], \quad (5.6)$$

where

$$\gamma_1 = -\frac{W_3}{6W_2^2} (\theta_2 - \theta_1)^2. \quad (5.7)$$

This approximation, with the appropriate prefactors taken from equations B.10, C.2, and C.4, is plotted in Figure 4a (dashed line) for the particular input considered in this figure.

As $\Delta t \rightarrow 0$, the exponential decay in equation 5.6 wins over the $\sim(\Delta t)^{-3}$ divergence for sufficiently small Δt . At larger values of Δt , the spike correlation function peaks and then decays algebraically. Hence, the neuron with the larger threshold tends to fire after the neuron with the lower threshold, with a typical latency given by the position of the peak. If we ignore the term $\gamma_1/\Delta t$, which is legitimate when the difference in thresholds is sufficiently small, the maximum is at $\Delta t = \Delta t^*$, where

$$\Delta t^* = \frac{\theta_2 - \theta_1}{\sqrt{-3W_2}}. \quad (5.8)$$

For the generating potential of equations 2.8 and 2.9,

$$\Delta t^* = \frac{\theta_2 - \theta_1}{\sigma} \sqrt{\frac{\tau_1 \tau_2}{3}}. \quad (5.9)$$

Equation 5.8 indicates that the most likely latency increases linearly with $\theta_2 - \theta_1$. An illustration of this result is shown in Figure 5, where f and w are as defined by equations 2.11 and 2.12, $\theta_2 = 0.5\sigma$, and $c(\Delta t)$ is plotted for three values of θ_1 : 0.2σ , -0.2σ , and -0.5σ (solid lines). With an increase in $\theta_2 - \theta_1$, the peak of the spike correlation function becomes wider and occurs at larger latencies. The arrows indicate the prediction for the position of the peak, equation 5.9, which matches the actual position very well even when $\theta_2 - \theta_1$ is relatively large.

$\Delta t < 0$: In this case the process g is required to have a positive derivative at $t = \Delta t < 0$, a negative derivative within the interval $(\Delta t, 0)$ and, again, a

⁶A weak asymmetry between positive and negative Δt exists also in the limit $\Delta t \rightarrow \infty$. This limit is considered in appendix B.

Figure 5: Spike correlation function, $c(\Delta t)/r_1 r_2$, for two model neurons with $\theta_2 = 0.5\sigma$ and $\theta_1 = 0.5\sigma$ (dashed line), 0.2σ , -0.2σ , and -0.5σ (solid lines). The generating potential is described by equations 2.5, 2.6, and 2.8. Arrows point to the position of the peak according to the prediction of equation 5.8.

positive derivative at $t = 0$. Such a trajectory becomes increasingly unlikely when $\Delta t \rightarrow 0$, and the spike correlation function decays to zero. The leading contribution is of the form

$$\log c(\Delta t) \simeq -\frac{3(\theta_1 - \theta_2)^2}{W_3(\Delta t)^3} + \dots \quad (5.10)$$

if $W_3 \neq 0$. If $W_3 = W_5 = 0$, the decay is even stronger, $\log c(\Delta t) \propto (\Delta t)^{-6}$ (see appendix C). Equation 5.10 introduces a characteristic timescale for the inhibition, scaling as

$$\frac{(\theta_1 - \theta_2)^{2/3}}{W_3^{1/3}} = \left(\frac{\tau_1^2 \tau_2^2}{\tau_1 + \tau_2} \right)^{1/3} \left(\frac{\theta_1 - \theta_2}{\sigma} \right)^{2/3}, \quad (5.11)$$

where the expression on the right-hand side holds if $w(\Delta t)$ is given by equation 2.9.

5.4 Partly Overlapping Inputs. We next generalize the analysis to the more realistic case where the inputs to different neurons are only partially overlapping:

$$g_i = f \circ (s + \xi_i). \quad (5.12)$$

The noise inputs ξ_i are assumed to be zero mean, jointly gaussian processes that are uncorrelated with s and with each other:

$$\langle \xi_i(t) \xi_j(t') \rangle = \alpha \sigma_0 \delta_{ij} \delta(t' - t). \quad (5.13)$$

Here α is the ratio between the standard deviation of the noise and that of the common stimulus. The covariance of the generating potentials is then

$$w_{ij}(\Delta t) = w(\Delta t)(1 + \alpha^2 \delta_{ij}). \quad (5.14)$$

The spike auto- and cross-correlation functions can be evaluated in a similar manner as for the noise-free case (see appendix B).

As an example, we consider the alpha filter, equation 2.11. In Figure 6 the standard deviation σ of the common stimulus is kept fixed, while α is varied. Figure 6a shows the spike correlation function of two model neurons with the same threshold $\theta = \sigma$ and with weak independent noise, $\alpha = 0.1$. The existence of noise increases the correlation in neural firing at nonzero latencies, compared to the noise-free case (dashed line). To understand this seemingly counterintuitive result, note that the spike correlation function in the noise-free case is identical to the spike autocorrelation function of a single neuron and includes a delta function contribution at $\Delta t = 0$. When the two neurons receive independent noise, they no longer fire precisely at the same time, leading to a broadening of the delta function into a peak of finite width.

Figure 6b shows the spike correlation function of two neurons with different thresholds, $\theta_1 = 0$ and $\theta_2 = \sigma$, for several values of α : 0 (no noise), 0.4, and 1. Increasing α reduces the correlation between the two neurons. Note, however, that the preference of neuron 2 to fire after neuron 1 is clearly evident at timescales comparable to τ , even when the noise and signal have the same standard deviation.

The inset shows $c(\Delta t)/r_1 r_2 - 1$ in a case where the noise is much larger than the signal, $\alpha = 10$. Here $c(\Delta t)$ is very well approximated using a linearization with respect to the cross-correlation function (dotted line), as described in appendix B, equation B.13. This approximation works quite well even if α is of order unity, as can be seen in the main plot of Figure 6b (dotted line).

6 Comparison with Integrate-and-Fire Neurons

Having characterized the spike correlation statistics of the threshold-crossing model, we may ask whether the results carry over to other models of neural firing. In even the simplest leaky integrate-and-fire (LIF) model, an analytical form is not known for the spike correlation functions. Hence the discussion in this section is based on numerical simulation of model

Figure 6: (a) Spike correlation function, $c(\Delta t)/r_1 r_2$, of two model neurons with identical thresholds $\theta = \sigma$, receiving an identical stimulus and uncorrelated noise, equation 5.12 (solid line.) The standard deviation of the noise, divided by that of the common stimulus, is $\alpha = 0.1$ (other parameters are described in the text). This is compared with the case where there is no noise, $\alpha = 0$ (dashed line.) (b) Spike correlation function of two neurons receiving similar input as in *a*, but differing in threshold: $\theta_1 = 0$ and $\theta_2 = \sigma$, where σ is the standard deviation of the common stimulus s . The correlation function is plotted for three different ratios between the noise standard deviation and the stimulus's standard deviation: $\alpha = 0, 0.4$, and 1 . The inset shows $c(\Delta t)/r_1 r_2 - 1$ in a case where the common stimulus is weak compared to the noise, $\alpha = 10$ (solid line). The dotted line in the inset and in the main plot (for $\alpha = 1$) is the approximation for the case of weak correlation, equation B.13.

Figure 7: (a) Spike cross-correlation function of two simulated LIF neurons, equations 4.3 and 4.4, with $\tau_1 = \tau_2 \equiv \tau$, and with thresholds 0.8σ and 1.0σ , receiving an identical stimulus (as described in the text, up to a baseline shift). In both neurons, $\theta - u_r = 0.5\sigma$. (b) Spike trains generated by the two LIF neurons (top two traces: black, $\theta_1 = 0.8$ and gray, $\theta_2 = 1$) and by threshold-crossing model neurons responding to the same stimulus (bottom two traces). Inset: blow-up of an interval showing a burst generated by the two LIF neurons.

neurons, using several variations of the LIF model. We focus on the relative timing of spikes elicited by neurons that receive the same stimulus but differ in their thresholds.

In the following examples, where we consider pairs of neurons that differ in θ , we suppose that the neurons are identical but differ in the mean value of their fluctuating input currents. Hence, after shifting the membrane potential to compensate for the different baseline currents, the reset potentials u_r in the two neurons differ, but the difference $\theta - u_r$ is kept fixed.

Figure 7a shows the spike correlation function of two such neurons, evaluated from simulation of model neurons according to the LIF model of equations 4.3 and 4.4, with $\theta_1 = 0.8\sigma$, $\theta_2 = \sigma$, and $\theta - u_r = 0.5\sigma$. The only difference between the LIF model and the threshold-crossing model is the

existence of a reset in the membrane potential following each spike. Nevertheless, comparing Figure 7a with Figure 4a reveals very little resemblance between the spike correlation functions obtained from the two models. Most notably, in the LIF model, there is almost no preference for one of the neurons to fire later than the other one.

To better understand this discrepancy, Figure 7b shows an example of spike trains generated by the two neurons in the LIF model (top two traces) and the threshold-crossing model (bottom two traces). Compared to the LIF model, which tends to produce bursts of spikes, the threshold-crossing model tends to generate much more isolated spikes.

The inset in Figure 7b shows an example of bursts of spikes generated by the LIF neurons after a relatively long silent period (top two traces). The first spike generated by the neuron with the smaller threshold (black) precedes the first spike generated by the neuron with the higher threshold (gray), preserving the tendency observed in the threshold-crossing model. This tendency is typically observed also in other isolated bursts.

Within the bursts, however, there is no clear relative timing of spikes of the two LIF neurons, because a spike in one neuron can be paired with a spike in the other neuron that either precedes it or comes after it. This suggests that the existence of bursts masks the tendency of the neurons to fire in a particular order. Motivated by these observations, we consider several situations in which the LIF model can exhibit a characteristic order of spike timing, similar to the prediction of the threshold-crossing model.

6.1 Sparse Firing. In situations where the LIF neurons fire isolated spikes, we may expect a clear order of spike timing to emerge and to be reflected in the spike correlation function.

6.1.1 Sparse Firing due to a Large Potential Reset, Compared to the Input Variance. With an increase of $\theta - u_r$, compared to σ , spikes tend to become more isolated. With fixed biophysical parameters of the cell, an increase in $(\theta - u_r)/\sigma$ corresponds to a decrease in the standard deviation of the fluctuating input current (see also appendix D). Figure 8a shows that as $(\theta - u_r)/\sigma$ increases in both neurons, a pronounced asymmetry develops in their spike cross-correlation function.

6.1.2 Sparse Firing due to Refractoriness. Sparse firing may result, alternatively, from the existence of an additional refractory mechanism. There are many possible ways to model refractoriness in a LIF model (Gerstner & Kistler, 2002), and here we consider one such possibility. After each spike, the membrane potential u is kept fixed at u_r during a waiting period whose length varies randomly from spike to spike. After the waiting period, the membrane potential continues to evolve according to equation 4.3, and the distribution function of waiting times decays exponentially with a time constant τ_r . Spike correlation functions, obtained from simulations of this model with $\tau_r = 2\tau$, are shown in Figure 8b for several pairs of thresholds,

Figure 8: (a) Spike cross-correlation functions of LIF neurons with increasing values $\theta - u_r$, the hyperpolarizing jump in potential following each spike (alternating solid and dashed lines: 0.5σ , 2σ , 4σ , and 6σ). In all traces, the thresholds are $\theta_1 = 0.8$ and gray, $\theta_2 = 1$. The trace for $\theta - u_r = 0.5\sigma$ is identical to the one in Figure 7a. (b) Spike cross-correlation functions of pairs of LIF neurons with refractoriness (as described in the main text). In all pairs, the second neuron has a threshold $\theta_2 = 1.0$, whereas the first neuron has a threshold $\theta_1 = 0.2$ (solid line), 0.5 (dashed line), 0.8 (solid line), and $\theta - u_r = 0.5\sigma$.

exhibiting a clear asymmetry in firing order. Note that in this example, the membrane time constant is shorter than the typical refractory time τ_r .

6.2 Bursting Events. Neurons often generate distinct bursts of spikes, sometimes referred to as events, when presented with stimuli possessing rapid temporal fluctuations (Berry et al., 1997; Berry & Meister, 1998b,

1998a). It has been argued that the timing of events, as marked by their first spike, can convey significant information about the stimulus (Hopfield, 1995; Gollisch & Meister, 2008). Hence it is of interest to understand the factors influencing the relative timing of these spikes. In the following, we consider a model where bursting events are more clearly separated from each other than in the simple LIF model. We then interpret the predictions of the threshold-crossing model in relation to the timing of burst onsets.

To reproduce well-separated spiking bursts in a neural model, we consider a generalization of the LIF model, introduced by Keat et al. (2001). This model was shown to reliably predict the structure of spike trains generated by retinal ganglion cells from several different species, in response to rapidly flickering stimuli. In a version of this model without noise, a generating potential $g(t)$ is related to the stimulus by equation 2.5, as in the threshold-crossing model. Spiking occurs when $g(t)$ crosses a time-dependent threshold $b(t)$ that increases following each spike:

$$b(t) = \theta + B \int_{-\infty}^t \chi(t') \exp\left(-\frac{t-t'}{\tau_p}\right) dt'. \quad (6.1)$$

We refer to this model as the variable-threshold (VT) model.

We may interpret $g - b + \theta$ as the neuron's membrane potential. With this interpretation, the discrete increase in b following a spike corresponds to a reset of the membrane potential from θ to $\theta - B$. The VT model is precisely equivalent to the LIF model of equations 4.3 and 4.4 if f is a double exponential filter, as in equation 2.8 and if $\tau_p = \tau_1$. For simplicity we take f to be an alpha filter, equation 2.11. However, we choose the timescale of threshold recovery τ_p to be larger than the neuron's membrane time constant, $\tau_p = 5\tau$. This ratio roughly matches the relation between τ_p and the shape of filters found in Keat et al. (2001) to provide a good description of spike trains from retinal ganglion cells.

A spike train generated by this model is shown in Figure 9b, and consists of clearly separated events. The tall vertical lines in Figure 9b represent spikes generated by a threshold-crossing model with the same generating potential and threshold as in the VT model. These spikes roughly match the onset of bursting events in the VT model. The threshold-crossing model thus provides a coarsely grained description of events generated by the VT model.

We next isolate the first spikes of events in the VT model by discarding any spike that occurred within a time delay $D = 2\tau$ from a previous spike.⁷ Figure 9c shows the cross-correlation function of these specifically selected spikes in several neurons with thresholds $\theta/\sigma = 0.5, 0.2, -0.2,$ and $-0.5,$

⁷Because the events are clearly separated from each other, the results are insensitive to the precise choice of D .

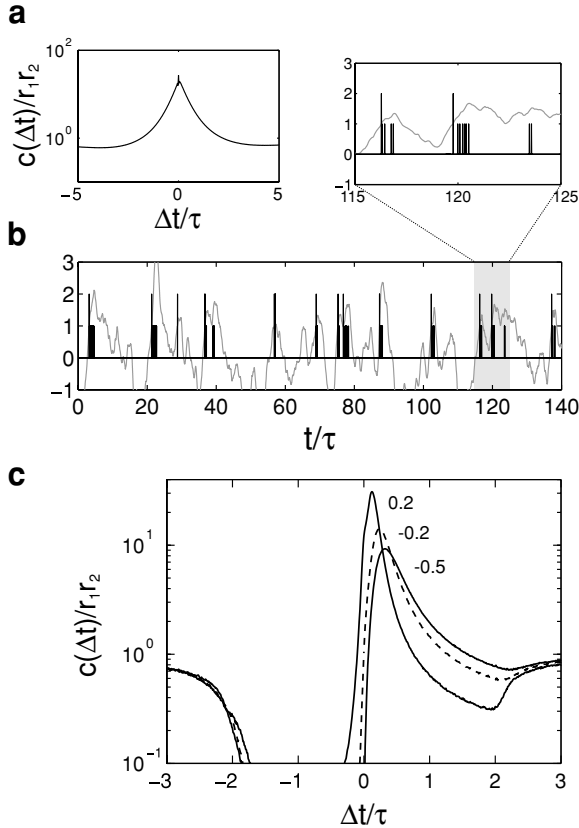

Figure 9: (a) Spike cross-correlation in the model described in section 6. The generating potential is described by equations 2.5, 2.8, and 2.9. The thresholds are $\theta_1 = 0.8\sigma$ and $\theta_2 = \sigma$, $\tau_p = 5\tau$ and $B = 0.1$. (b) An example of a spike train generated by this model (short vertical lines). The threshold $\theta = \sigma$. For comparison, the tall vertical lines represent spike times in the threshold-crossing model. The generating potential, common to both models, is plotted in gray. Top right: blow-up of a shorter interval, showing three spiking events. (c) Cross-correlation of event times in the same model, between a model neuron with threshold $\theta_1 = 0.5$ and three model neurons with thresholds $\theta_2 = 0.2, -0.2$, and -0.5 . Other parameters are as in *a* and *b*. Event onsets are isolated by discarding any spike that occurs within a time frame of 2τ from a previous spike.

which were all presented with the same stimulus. These cross-correlation functions display a strong asymmetry between positive and negative Δt and are qualitatively very similar to the spike cross correlations in the threshold-crossing model shown in Figure 5. In contrast the spike

cross-correlation functions calculated directly from all the spikes, Figure 9a, are very different from the prediction of the threshold-crossing model.

These results suggest that the onsets of bursting events in neurons that receive the same stimulus, but differ in their threshold, can exhibit strong asymmetry in their relative timing and that the correlation functions of these event onsets can be qualitatively described by the simplified threshold-crossing model.

7 Summary

We considered in this work a relatively simple deterministic process that produces a discrete spike train from an analog, continuous signal. The timing of spikes in this model is more precisely controlled by the stimulus than typically predicted by rate-based models. This aspect of the model is motivated by observations of precisely timed spiking in neural assays, particularly in response to stimuli that possess strong temporal modulations (Mainen & Sejnowski, 1995; Berry et al., 1997; de Ruyter van Steveninck et al., 1997; Meister & Berry, 1999; Uzzell & Chichilnisky, 2004). Some of the salient properties of spike correlation functions in this model are summarized below.

Most notably, two neurons receiving identical inputs can show a preference for one neuron to fire later than the other, although there is no monosynaptic connectivity between them (see Figures 4a and 5). This preference is prominent even if the thresholds of the two neurons are similar (but not equal), and if there is only partial overlap in their input (see Figure 6.)

Comparison with the leaky integrate-and-fire model shows that bursting in LIF neurons often masks the preference of neurons to fire in a particular order (see Figure 7). However, there are several situations in which such a preference may be observed in LIF neurons. First, LIF neurons can display a preference to fire in a particular order if they produce sparse spiking, for example, due to a large hyperpolarizing step in the membrane potential after each spike, compared to the standard deviation of the stimulus, or due to other sources of refractoriness (see Figure 8). Second, when the neurons generate clearly separated bursting events, the first spikes of these events have cross-correlation functions that are similar to those predicted by the threshold crossing model (see Figure 9).

The spike cross-correlation function of neurons that differ only in their thresholds may be probed experimentally by repeatedly presenting the same stimulus to a single neuron, while injecting varying amounts of current into the neuron from trial to trial. Correlations between different trials can then effectively measure the spike correlation function of two identical neurons with different thresholds. This approach was recently taken in Markowitz, Collman, Brody, and Hopfield (2008), where a gaussian stimulus, mimicking the spectral properties of gamma oscillations, was injected into rat pyramidal neurons from the somatosensory cortex. While spike cross-correlation functions are not shown in Markowitz et al. (2008), spike

trains from different trials exhibit a clear modulation of spike timing by the varying injected current, suggesting that a strong asymmetry exists in the spike correlation function of neurons with different thresholds. Furthermore, the characteristic latency between the firing of two neurons appears to increase linearly as a function of the difference in injected currents. This roughly linear dependence persists over a wide range of current differences, similar to our results from the threshold-crossing model.

We also considered in this work the spike-triggered average stimulus (STA). The STA in our model is a linear combination of the filter and its derivative. A simple geometrical argument shows that this result extends to a larger class of models: it should hold whenever the stimulus is passed through a linear kernel, if spike decisions are then based strictly on the output of the kernel and its derivative. Varying the threshold modifies the relative weight of the filter and its derivative (see Figure 1). It will be interesting to probe for such a dependence of the STA on threshold in real neurons.

Note

Tchumatchenko, Malyshev, Geisel, Volgushev, and Wolf (2008) have recently considered a threshold-crossing model, similar to the one presented in this letter. A preprint of their work was made available on the arXiv.org e-Print archive while our manuscript was in review.

Appendix A: Spike-Triggered Average Stimulus and Covariance

To avoid infinities in the calculation, we assume first that s is a correlated gaussian process with a correlation function $w_s(\Delta t)$. At the end of the calculation, we take the limit

$$w_s(\Delta t) \rightarrow \sigma_0^2 \delta(t - t'). \quad (\text{A.1})$$

The correlation function of g is

$$w(\Delta t) = \int dt \int dt' f(t) w_s(t - t' + \Delta t) f(t'). \quad (\text{A.2})$$

To evaluate f_{STA} , we need the joint probability distribution function for $g(0) = \theta$, $\dot{g}(0) = q_1$, and $s(\Delta t) = s_2$, in terms of which f_{STA} is given by

$$f_{\text{STA}}(\Delta t) = \frac{1}{r} \int_{-\infty}^{\infty} ds_2 \int_0^{\infty} dq_1 s_2 \cdot q_1 \cdot p(\theta, q_1; s_2). \quad (\text{A.3})$$

The joint probability distribution of $p(\theta, q_1; s_2)$ is given by

$$p(\theta, q_1; s_2) = \frac{1}{Z} \exp \left[-\frac{1}{2} \boldsymbol{\xi}^T A^{-1} \boldsymbol{\xi} \right], \quad (\text{A.4})$$

where $\zeta^T = (\theta, q_1, s_2)$, $Z = [(2\pi)^n \det A]^{1/2}$, and

$$A = \begin{bmatrix} w(0) & 0 & (f \circ w_s)(-\Delta t) \\ 0 & -w''(0) & (f' \circ w_s)(-\Delta t) \\ (f \circ w_s)(-\Delta t) & (f' \circ w_s)(-\Delta t) & w_s(0) \end{bmatrix}. \quad (\text{A.5})$$

Evaluating the integral, equation A.3 yields

$$f_{\text{STA}}(\Delta t) = \frac{\theta}{w(0)} (f \circ w_s)(-\Delta t) + \sqrt{\frac{\pi}{-2w''(0)}} (f' \circ w_s)(-\Delta t). \quad (\text{A.6})$$

In the limit where w_s is uncorrelated, equation A.1, we get equation 4.2.

The spike-triggered covariance $C(t_1, t_2)$ is defined as

$$C(t_1, t_2) = \frac{1}{r} \langle [s(t_1) - f_{\text{STA}}(t_1)][s(t_2) - f_{\text{STA}}(t_2)] \cdot \chi(0) \rangle. \quad (\text{A.7})$$

A calculation similar to that outlined for the STA yields

$$\frac{C(t_1, t_2)}{\sigma_0^2} = -\frac{f(-t_1)f(-t_2)}{w(0)} + \frac{f'(-t_1)f'(-t_2)}{-w''(0)} \left(1 - \frac{\pi}{2}\right) + \delta(t_2 - t_1). \quad (\text{A.8})$$

The eigenfunctions $\psi_i(t)$ of the covariance operator and their corresponding eigenvalues λ_i are determined by the equation

$$\int C(t_1, t_2) \psi_i(t_2) dt_2 = \lambda_i \psi_i(t_1). \quad (\text{A.9})$$

From equation A.8, we see that there are only two eigenfunctions $\psi_{1,2}(\Delta t)$ with eigenvalues that differ from σ_0^2 . (The significance of these eigenfunctions is that the variance of the stimulus's projection on $\psi_{1,2}$, when conditioned on the occurrence of a spike at $t = 0$, is different from its nominal value of σ_0^2 .) The first eigenfunction $\psi_1(\Delta t)$ is proportional to $f(-\Delta t)$. Because the generating potential must be equal to the threshold at $t = 0$, when a spike is produced, the variance of the stimulus's projection on f must be zero. Indeed, $\lambda_1 = 0$. The second eigenfunction $\psi_2(\Delta t) \propto f'(-\Delta t)$, and $\lambda_2 = (2 - \pi/2)\sigma_0^2$.

Appendix B: Spike Correlations

We consider two model neurons that may differ in their generating potentials $g_{1,2}$ and in their thresholds $\theta_{1,2}$. The generating potentials $g_{1,2}$ are

assumed to be jointly gaussian and stationary, characterized by correlation functions

$$w_{ij}(\Delta t) = \langle g_i(0)g_j(\Delta t) \rangle. \quad (\text{B.1})$$

The stationary nature of $g_{1,2}$ implies that $w_{11}(-\Delta t) = w_{11}(\Delta t)$ and that, similarly, $w_{22}(-\Delta t) = w_{22}(\Delta t)$. For the cross-correlation functions, it implies only that $w_{12}(-\Delta t) = w_{21}(\Delta t)$. In the rest of this appendix, we assume that, in addition,

$$w_{12}(\Delta t) = w_{21}(\Delta t), \quad (\text{B.2})$$

which is correct throughout section 5. In this case, the expressions for the joint probability distribution and the spike correlation function simplify considerably.

We first need to evaluate the joint probability distribution for $g_1(0) = \theta_1$, $\dot{g}_1(0) = q_1$, $g_2(\Delta t) = \theta_2$, and $\dot{g}_2(\Delta t) = q_2$. This is given by

$$p(\theta_1, q_1; \theta_2; q_2) = \frac{1}{Z} \exp \left[-\frac{1}{2} \boldsymbol{\zeta}^T A^{-1} \boldsymbol{\zeta} \right], \quad (\text{B.3})$$

where $\boldsymbol{\zeta}^T = (\theta_1, q_1, \theta_2, q_2)$, $Z = [(2\pi)^n \det A]^{1/2}$, and

$$A = \begin{bmatrix} w_{11}(0) & 0 & w_{12}(\Delta t) & w'_{12}(\Delta t) \\ 0 & -w''_{11}(0) & -w'_{12}(\Delta t) & -w''_{12}(\Delta t) \\ w_{12}(\Delta t) & -w'_{12}(\Delta t) & w_{22}(0) & 0 \\ w'_{12}(\Delta t) & -w''_{12}(\Delta t) & 0 & -w''_{22}(0) \end{bmatrix}. \quad (\text{B.4})$$

Since in calculating the spike correlation function, θ_1 and θ_2 are kept fixed, it is useful to reexpress this quantity as a quadratic function of q_1 and q_2 alone. We know that

$$\int dq_1 \int dq_2 p(\theta_1, q_1; \theta_2, q_2) = p(\theta_1; \theta_2), \quad (\text{B.5})$$

where $p(\theta_1; \theta_2)$ is the joint probability distribution of $g_1(0) = \theta_1$, $g_2(\Delta t) = \theta_2$,

$$p(\theta_1; \theta_2) = \frac{1}{2\pi D} \exp \left(-\frac{w_{11}(0)\theta_1^2 + w_{22}(0)\theta_2^2 - 2w_{12}(\Delta t)\theta_1\theta_2}{2D^2} \right), \quad (\text{B.6})$$

and

$$D = [w_{11}(0)w_{22}(0) - w_{12}^2(\Delta t)]^{1/2}. \quad (\text{B.7})$$

Hence, we can rewrite $p(\theta_1, q_1; \theta_2, q_2)$ as

$$p = p(\theta_1; \theta_2) \times \frac{(\det m^{-1})^{1/2}}{2\pi} \exp \left[-\frac{1}{2} (\mathbf{q} - \mathbf{q}_0)^T m^{-1} (\mathbf{q} - \mathbf{q}_0) \right].$$

The matrix m and \mathbf{q}_0 are found by collecting the quadratic and linear terms in q_1, q_2 in equation B.3,

$$m = \begin{bmatrix} -w''_{11}(0) & -w''_{12}(\Delta t) \\ -w''_{12}(\Delta t) & -w''_{22}(0) \end{bmatrix} - \frac{[w'_{12}(\Delta t)]^2}{w_{11}(0)w_{22}(0) - w_{12}^2(\Delta t)} \begin{bmatrix} w_{11}(0) & w_{12}(\Delta t) \\ w_{12}(\Delta t) & w_{22}(0) \end{bmatrix}, \quad (\text{B.8})$$

and

$$\mathbf{q}_0 = \frac{w'_{12}(\Delta t)}{w_{11}(0)w_{22}(0) - w_{12}^2(\Delta t)} \begin{bmatrix} w_{12}(\Delta t)\theta_1 - w_{11}(0)\theta_2 \\ w_{22}(0)\theta_1 - w_{12}(\Delta t)\theta_2 \end{bmatrix}. \quad (\text{B.9})$$

Finally, we can write the spike correlation function as

$$c(\Delta t) = p(\theta_1; \theta_2) \cdot I, \quad (\text{B.10})$$

where

$$I = \frac{(\det m^{-1})^{1/2}}{2\pi} \int_0^\infty dq_1 \int_0^\infty dq_2 q_1 \cdot q_2 \cdot \exp \left[-\frac{1}{2} (\mathbf{q} - \mathbf{q}_0)^T m^{-1} (\mathbf{q} - \mathbf{q}_0) \right] \quad (\text{B.11})$$

B.1 Nearly Independent Inputs. When the cross-correlation $w_{12}(\Delta t)$ is small compared to the autocorrelations $w_{11}(0)$, $w_{22}(0)$, I , and p can be expanded in powers of $w_{12}(\Delta t)$ and its derivatives. If $w_{12}(\Delta t) = 0$, the matrix m is diagonal, $p(\theta_1, q_1; \theta_2, q_2) = p(\theta_1, q_1) \cdot p(\theta_2, q_2)$, and $c(\Delta t) = r_1 r_2$. To first order in $w_{12}(\Delta t)$,

$$I \simeq I_0 - \frac{1}{4} w''_{12}(\Delta t) + \frac{1}{2\sqrt{2\pi}} \times \left\{ \frac{[-w''_{11}(0)]^{1/2}}{w_{22}(0)} \theta_1 - \frac{[-w''_{22}(0)]^{1/2}}{w_{11}(0)} \theta_2 \right\} w'_{12}(\Delta t) + \dots, \quad (\text{B.12})$$

where $I_0 = [w''_{11}(0)w''_{22}(0)]^{1/2}/(2\pi)$. By similarly expanding $p(\theta_1; \theta_2)$, we find that

$$\begin{aligned} \frac{c(\Delta t) - r_1 r_2}{r_1 r_2} &\simeq \frac{\theta_1 \theta_2}{w_{11}(0)w_{22}(0)} w_{12}(\Delta t) - \frac{\pi}{2[w''_{11}(0)w''_{22}(0)]^{1/2}} w'_{12}(\Delta t) \\ &+ \sqrt{\frac{\pi}{2}} \left\{ \frac{\theta_1}{[-w''_{22}(0)]^{1/2} w_{22}(0)} - \frac{\theta_2}{[-w''_{11}(0)]^{1/2} w_{11}(0)} \right\} w'_{12}(\Delta t). \end{aligned} \quad (\text{B.13})$$

B.2 Identical Inputs. Equation B.11 can be further simplified in the case where g_1 and g_2 are identical. In this case, $w_{11} = w_{12} = w_{21} = w_{22} \equiv w$. The spike correlation function involves five parameters: w and its second derivative at zero, w' , its derivative, and its second derivative at Δt . In equation B.11, m and \mathbf{q}_0 , equations B.8 and B.9 are then

$$m = \begin{bmatrix} -w''(0) & -w''(\Delta t) \\ -w''(\Delta t) & -w''(0) \end{bmatrix} - \frac{[w'(\Delta t)]^2}{w^2(0) - w^2(\Delta t)} \begin{bmatrix} w(0) & w(\Delta t) \\ w(\Delta t) & w(0) \end{bmatrix}, \quad (\text{B.14})$$

$$\mathbf{q}_0 = \frac{w'(\Delta t)}{w^2(0) - w^2(\Delta t)} \begin{bmatrix} w(\Delta t)\theta_1 - w(0)\theta_2 \\ w(0)\theta_1 - w(\Delta t)\theta_2 \end{bmatrix}, \quad (\text{B.15})$$

and

$$\begin{aligned} p(\theta_1; \theta_2) &= \frac{1}{2\pi [w(0)^2 - w(\Delta t)^2]^{1/2}} \\ &\cdot \exp \left\{ -\frac{w(0)(\theta_1^2 + \theta_2^2) - 2w(\Delta t)\theta_1\theta_2}{2[w(0)^2 - w(\Delta t)^2]} \right\}. \end{aligned} \quad (\text{B.16})$$

Note that from symmetry under time reversal, we must have

$$p(\theta_1, q_1; \theta_2, q_2) = p(\theta_2, -q_2; \theta_1, -q_1). \quad (\text{B.17})$$

This symmetry is reflected in the fact that $(\mathbf{q}_0)_{1,2}(\theta_1, \theta_2) = -(\mathbf{q}_0)_{2,1}(\theta_2, \theta_1)$.

Because $m_{11} = m_{22}$, the eigenvectors of m are

$$\mathbf{v}_{\pm} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm 1 \end{pmatrix}, \quad (\text{B.18})$$

and the corresponding eigenvalues are

$$m_{\pm} = -w''(0) \mp w''(\Delta t) + \frac{[w'(\Delta t)]^2}{w^2(0) - w^2(\Delta t)} [-w(0) \mp w(\Delta t)]. \tag{B.19}$$

It is useful to rewrite I in the coordinates in which m is diagonal,

$$u_{\pm} = \frac{1}{\sqrt{2}}(q_1 \pm q_2), \tag{B.20}$$

in terms of which

$$I = \frac{1}{2} \int_0^{\infty} du_+ \int_{-u_+}^{u_+} du_- (u_+^2 - u_-^2) \times \frac{1}{2\pi m_+^{1/2} m_-^{1/2}} \exp \left[-\frac{(u_+ - u_{0,+})^2}{2m_+} - \frac{(u_- - u_{0,-})^2}{2m_-} \right], \tag{B.21}$$

where

$$u_{0,\pm} = -\frac{1}{\sqrt{2}} \frac{w'(\Delta t)}{w(0) \mp w(\Delta t)} (\theta_2 \mp \theta_1). \tag{B.22}$$

The inner integral can be expressed using the gauss error function, yielding an expression for I that involves a single integral,

$$I = \int_0^{\infty} du_+ \frac{1}{4\pi m_+^{1/2}} \exp \left[-\frac{(u_+ - u_{0,+})^2}{2m_+} \right] \times \left\{ m_-^{1/2} (u_+ - u_{0,-}) \exp \left[-\frac{(u_+ + u_{0,-})^2}{2m_-} \right] + m_-^{1/2} (u_+ + u_{0,-}) \exp \left[-\frac{(u_+ - u_{0,-})^2}{2m_-} \right] + \sqrt{\frac{\pi}{2}} (m_- + u_{0,-}^2 - u_+^2) \left[\operatorname{erf} \left(\frac{u_{0,-} - u_+}{\sqrt{2m_-}} \right) - \operatorname{erf} \left(\frac{u_{0,-} + u_+}{\sqrt{2m_-}} \right) \right] \right\}. \tag{B.23}$$

B.3 The Limit $\Delta t \rightarrow \infty$. Assuming that w and all its derivatives at $t = \Delta t$ tend to zero when $\Delta t \rightarrow \infty$, the probability distributions at $t = 0$ and at $t = \Delta t$ decouple, and to leading order $c(\Delta t) \rightarrow r_1 r_2$.

To evaluate the deviation from independent spiking, we can use equation B.13 in the case where $w_{11} = w_{22} = w_{12} = w_{21} \equiv w$:

$$\begin{aligned} \frac{c(\Delta t) - r_1 r_2}{r_1 r_2} &\simeq \frac{\theta_1 \theta_2}{w(0)^2} w(\Delta t) + \frac{\pi}{2w''(0)} w''(\Delta t) \\ &+ \frac{1}{w(0)} \left[\frac{\pi}{-2w''(0)} \right]^{1/2} (\theta_1 - \theta_2) w'(\Delta t). \end{aligned} \quad (\text{B.24})$$

The third term in this equation is antisymmetric in Δt and in $\theta_1 - \theta_2$. Because $w'(\Delta t)$ is typically negative for positive Δt , this term represents a small preference for the neuron with the higher threshold to spike after the neuron with the lower threshold.

Appendix C: The Limit $\Delta t \rightarrow 0$

We consider here the limit $\Delta t \rightarrow 0$ in the case of identical inputs. In this limit, the matrix m becomes singular, requiring particular analysis in order to evaluate the correlation matrix.

The argument of the exponential in equation 5.2 is maximal when $\mathbf{q} = \mathbf{q}_0$ (see equation B.15), which approaches, when $\Delta t \rightarrow 0$,

$$(q_0)_{1,2} \rightarrow \frac{\theta_2 - \theta_1}{\Delta t}. \quad (\text{C.1})$$

This is the derivative of $g(t)$ if it follows a linear trajectory from $g(0) = \theta_1$ to $g(\Delta t) = \theta_2$. However, this maximum is within the integration range in equation 5.2 only if $(\theta_2 - \theta_1)/\Delta t$ is positive, that is, only if the neuron with the higher threshold spikes after the neuron with the lower threshold. Accordingly, the behavior of $c(\Delta t)$ is substantially different for positive and negative Δt .

For simplicity of notation in this appendix, we assume that $\Delta t > 0$ and that $\theta_2 - \theta_1$ may be positive, negative, or zero. To relate this to the presentation in section 5, where we assumed that $\theta_2 - \theta_1$ is positive, recall that $c(-\Delta t)$ is the same as $c(\Delta t)$ with the two thresholds θ_1, θ_2 exchanged.

To evaluate the behavior of the integral I at small Δt , we need to expand the expressions for m_+, m_-, u_+ , and u_- in this limit, where we use the representation of I in equations B.21 and B.22. The leading terms in these expansions are shown in Table 1 in two cases: $W_3 \neq 0$ and All W_i with odd index vanish.

C.1 The Case $\theta_2 - \theta_1 > 0$. This case is most simply treated in the original (\mathbf{q}) coordinates. As $\Delta t \rightarrow 0$ $(q_0)_{1,2} \sim (\Delta t)^{-1}$ whereas the standard deviation of the gaussian in equation 5.2 tends to zero as $\sqrt{\Delta t}$ in both of the principal directions (or faster if $W_3 = 0$). We can therefore replace the lower

Table 1: Leading-Order Terms in the Expansion of m_{\pm} and u_{\pm} for Small Δt .

	$W_3 \neq 0$	$W_3 = W_5 = 0$
m_+	$\frac{W_3}{3} \Delta t$	$\frac{1}{72} \left(\frac{W_4^2}{W_2} - W_6 \right) (\Delta t)^4$
m_-	$W_3 \Delta t$	$\frac{1}{2} \left(-\frac{W_2^2}{W_0} + W_4 \right) (\Delta t)^2$
$\sqrt{2}u_+$	$(\theta_2 - \theta_1) \frac{2}{\Delta t}$	$(\theta_2 - \theta_1) \frac{2}{\Delta t}$
$\sqrt{2}u_-$	$-(\theta_1 + \theta_2) \frac{W_2}{2W_0} \Delta t$	$-(\theta_1 + \theta_2) \frac{W_2}{2W_0} \Delta t$

Note: If $\theta_1 = \theta_2$, $u_{\pm} = 0$ to all orders.

integration limits by $-\infty$ with an exponentially small error. Furthermore, the integral in equation 5.2 becomes dominated by the peak of the gaussian as it becomes sharper with the decrease of Δt .

To leading order in Δt , the integral is thus simply

$$I \simeq (q_0)_1 \cdot (q_0)_2 = \frac{(\theta_2 - \theta_1)^2}{\Delta t^2}. \tag{C.2}$$

To evaluate $p(\theta_1; \theta_2)$, we note that in equation B.16,

$$w^2(0) - w^2(\Delta t) \simeq -W_0 W_2 (\Delta t)^2, \tag{C.3}$$

and by expanding the argument of the exponential, we obtain

$$p(\theta_1; \theta_2) \simeq \frac{1}{2\pi(-W_0 W_2)^{1/2} |\Delta t|} \times \exp \left[\frac{1}{2W_2} \left(\frac{\theta_2 - \theta_1}{\Delta t} \right)^2 + \frac{\gamma_1}{\Delta t} + \gamma_0 \right], \tag{C.4}$$

where

$$\gamma_0 = \frac{1}{72W_2^3} (4W_3^2 - 3W_2 W_4) (\theta_2 - \theta_1)^2 - \frac{1}{8W_0} (\theta_1 + \theta_2)^2 \tag{C.5}$$

and

$$\gamma_1 = -\frac{W_3}{6W_2^2} (\theta_2 - \theta_1)^2. \tag{C.6}$$

The leading contribution in equation C.4 is proportional to the probability density to have a derivative equal to $(\theta_2 - \theta_1)/\Delta t$. Combining equations C.2 and C.4, we obtain the small Δt behavior of $c(\Delta t)$, equation 5.6.

When $\theta_2 - \theta_1 \rightarrow 0$, the peak in the spike correlation function gradually becomes the delta function contribution to the spike autocorrelation

function, equation 5.3. For sufficiently small $\theta_2 - \theta_1$ and for $\Delta t \lesssim -W_2/W_3$, the spike correlation function is approximately

$$c(\Delta t) \simeq \frac{(\theta_2 - \theta_1)^2}{2\pi(-W_0W_2)^{1/2}\Delta t^3} \times \exp\left[-\frac{\theta^2}{2W_0} + \frac{1}{2W_2}\left(\frac{\theta_2 - \theta_1}{\Delta t}\right)^2\right]. \quad (\text{C.7})$$

The integral of this function from 0 to infinity is equal to r , whereas the width of the peak and its position both tend to zero when $\theta_2 - \theta_1 \rightarrow 0$. Hence, the small Δt behavior of the spike correlation function approaches, when $\theta_2 - \theta_1 \rightarrow 0$,

$$r\delta(\Delta t). \quad (\text{C.8})$$

C.2 The Case $\theta_2 = \theta_1$. The maximum of the gaussian in equation B.21 is at $u_+ = 0$ and $u_- \sim \theta\Delta t$ (where $\theta \equiv \theta_1 = \theta_2$), which lies outside the range of integration (the (+,+) quadrant in the \mathbf{q} coordinates). However, if $W_3 \neq 0$, the distance from the (+,+) quadrant is small compared to the standard deviation of the gaussian ($\sim\sqrt{\Delta t}$). As a result, the integral in equation B.21 can be treated as if $u_{0,\pm} = 0$. The situation is different if $W_3 = 0$, in which case the distance of \mathbf{q} from the origin and the standard deviation in the u_- direction are of the same order of magnitude.

C.2.1 $W_3 \neq 0$. In this case we have, to leading order in Δt ,

$$\begin{aligned} I &\simeq \frac{1}{4\pi m_+^{1/2} m_-^{1/2}} \int_0^\infty du_+ \int_{-u_+}^{u_+} du_- (u_+^2 - u_-^2) \exp\left(-\frac{u_+^2}{2m_+} - \frac{u_-^2}{2m_-}\right) \\ &= \frac{1}{2\pi} \left[(m_+ m_-)^{1/2} + (m_+ - m_-) \arctan \sqrt{\frac{m_+}{m_-}} \right] \simeq \frac{W_3 \Delta t}{2\pi \sqrt{3}} \left[1 - \frac{\pi}{3\sqrt{3}} \right]. \end{aligned} \quad (\text{C.9})$$

For small Δt ,

$$p(\theta; \theta) \simeq \frac{1}{2\pi \sqrt{-W_0W_2}\Delta t} \exp\left(-\frac{\theta^2}{2W_0}\right). \quad (\text{C.10})$$

Hence the spike correlation function tends to a finite value when $\Delta t \rightarrow 0$, equation 5.4.

C.2.2 $W_3 = W_5 = 0$. To treat this case, we rescale u_\pm by the leading dependence on Δt in the expansion of $(m_\pm)^{1/2}$ (this procedure can also be applied in the case $W_3 \neq 0$, in order to derive equation C.9 in a more formal manner). We use the following notation,

$$\begin{aligned} m_+ &\simeq a_+(\Delta t)^4; & m_- &\simeq a_-(\Delta t)^2 \\ u_+ &= \tilde{u}_+ \cdot (\Delta t)^2; & u_- &= \tilde{u}_- \cdot \Delta t; & u_{-,0} &\simeq \alpha \Delta t, \end{aligned} \quad (\text{C.11})$$

where

$$a_+ = \frac{1}{72} \left(\frac{W_4^2}{W_2} - W_6 \right); \quad a_- = \frac{1}{2} \left(-\frac{W_2^2}{W_0} + W_4 \right)$$

$$\alpha = -\frac{W_2}{\sqrt{2}W_0} \theta, \tag{C.12}$$

and obtain

$$I \simeq \frac{1}{4\pi(a_+a_-)^{1/2}} \int_0^\infty d\tilde{u}_+ \int_{-\tilde{u}_+\Delta t}^{\tilde{u}_+\Delta t} d\tilde{u}_- [(\Delta t)^4 \tilde{u}_+^2 - (\Delta t)^2 \tilde{u}_-^2]$$

$$\times \exp \left[-\frac{\tilde{u}_+^2}{2a_+} - \frac{(\tilde{u}_- - \alpha)^2}{2a_-} \right]$$

$$\simeq \frac{2}{3\pi} (\Delta t)^5 \sqrt{\frac{a_+^3}{a_-}} \exp \left(-\frac{\alpha^2}{2a_-} \right). \tag{C.13}$$

Using equation C.10, we see that in contrast to the case $W_3 \neq 0$, the spike correlation function tends to zero when $\Delta t \rightarrow 0$:

$$c(\Delta t) \sim (\Delta t)^4. \tag{C.14}$$

C.3 The Case $\theta_2 - \theta_1 < 0$. In this case, as in the case $\theta_2 > \theta_1$, $(q_0)_{1,2} \sim \Delta t^{-1}$, but now \mathbf{q}_0 is outside the integration region, far from it on the scale of the gaussian's standard deviation. We denote

$$u_{+,0} \simeq -\frac{\alpha}{\Delta t}, \tag{C.15}$$

where $\alpha = \sqrt{2}(\theta_1 - \theta_2) > 0$. It is then seen from equation B.21 that I decays to zero exponentially, with a leading contribution of the form

$$\log(I) \simeq -\frac{\alpha^2}{2m_+(\Delta t)^2} = -\frac{1}{m_+} \left(\frac{\theta_1 - \theta_2}{\Delta t} \right)^2, \tag{C.16}$$

which corresponds, if $W_3 \neq 0$, to

$$\log(I) \simeq -\frac{3(\theta_1 - \theta_2)^2}{W_3(\Delta t)^3} + \dots \tag{C.17}$$

and, if $W_3 = W_5 = 0$, to

$$\log(I) \simeq -\frac{(\theta_1 - \theta_2)^2}{a_+(\Delta t)^6} + \dots \quad (\text{C.18})$$

In contrast to I in the case $\theta_2 - \theta_1 > 0$, which diverges when $\Delta t \rightarrow 0$, in the case $\theta_2 - \theta_1 < 0$, I strongly decays to zero. A more precise treatment of this integral requires evaluation of additional terms in the expansion shown in Table 1.

The probability $p(\theta_1; \theta_2)$ is the same as in the case $\theta_2 - \theta_1 > 0$. Like I , p decays exponentially when $\Delta t \rightarrow 0$, but the leading power of $(\Delta t)^{-1}$ inside the exponential is smaller, so it becomes relevant only if $\log I$ is expanded beyond the leading order.

Appendix D: Parameterization of the LIF Model

The notation in equations 4.3 and 4.4 was chosen for mathematical simplicity. To see how the parameters in these equations are related to biophysical properties of the neuron, we start with a standard equation for the membrane potential dynamics of an LIF neuron (Dayan & Abbott, 2001),

$$\tau_1 \frac{dv}{dt} = E_0 - v + R_m I_c, \quad (\text{D.1})$$

where E_0 is the resting potential of the cell, R_m is the membrane resistance, and I_c is the input current. Further, the potential v resets to v_r whenever it reaches a threshold v_θ .

To reparameterize this equation as in equation 4.3, we first define

$$I = R_m(I_c - \langle I_c \rangle), \quad (\text{D.2})$$

where $\langle I_c \rangle$ is the mean (baseline) value of the fluctuating current I_c . Due to the multiplication by R_m , I has the same units as the potential u . Second, we shift the potential v by defining

$$u = v - E_0 - R_m \langle I_c \rangle. \quad (\text{D.3})$$

With these definitions, we obtain equation 4.3, repeated here,

$$\tau_1 \frac{du}{dt} = -u + I, \quad (\text{D.4})$$

where I has zero mean and $\theta - u_r = v_\theta - v_r$.

The properties of the spike train depend on the ratio between $\theta - u_r$ and the standard deviation σ . The following example demonstrates what is a

reasonable range of values for this ratio. The standard deviation of I is equal to $\sqrt{2}\sigma$ (assuming that $\tau_1 = \tau_2$). Suppose that the standard deviation of the current I_c is 0.1 nA. Assuming that $R_m = 100 \text{ M}\Omega$ (which corresponds to a neuron with surface area 10^{-4} cm^2 and membrane time constant $\tau_1 = 10 \text{ ms}$), and that the difference between the threshold membrane potential and the reset potential is 10 mV, we get, using equation D.2, $\theta - u_r \simeq 0.7\sigma$.

The ratio $(\theta - u_r)/\sigma$ may vary depending on the biophysical parameters of the cell. More importantly, this ratio can vary considerably depending on the standard deviation of the fluctuating current: a smaller standard deviation of the fluctuating input corresponds to a larger value of $(\theta - u_r)/\sigma$.

Appendix E: Correlations in the LN Model

In the LN model, the spike times are an inhomogeneous Poisson process, with a rate given by

$$r(t) = \phi[(f \circ s)(t)], \quad (\text{E.1})$$

where ϕ may be regarded as the transfer function of the neuron, if we think of s as a direct input to the neuron (more generally, we may think of equation E.1 as a phenomenological relation between stimulus and firing rate).

If there was no nonlinearity [$\phi(x) = x$], we would have $\langle r(t)r(t') \rangle \sim w(t - t')$, where w is the autocorrelation function of $f \circ s$. More generally, we need to take into account the particular form of ϕ . We focus here on the case where two neurons, labeled 1 and 2, receive the same input and have the same filter but possibly differ in the nonlinear function ϕ . As in previous sections, we assume that the stimulus s is gaussian (and so is $g = f \circ s$). We then have

$$c(\Delta t) = \int_{-\infty}^{\infty} dg_1 \int_{-\infty}^{\infty} dg_2 \phi_1(g_1)\phi_2(g_2)p(g_1; g_2), \quad (\text{E.2})$$

where $p(g_1; g_2)$ is given by equation B.16. The spike correlation function thus depends on $w(0)$ and on $w(\Delta t)$: in comparison, in the threshold-crossing model, it depends also on the first and second derivatives of w at these two points.

For example, if

$$\phi_{1,2}(g) = \phi_0 \begin{cases} 0, & g < \theta_{1,2} \\ g - \theta_{1,2}, & g > \theta_{1,2} \end{cases}, \quad (\text{E.3})$$

the spike correlation function is

$$c(\Delta t) = \phi_0^2 \int_{\theta_1}^{\infty} dg_1 \int_{\theta_2}^{\infty} dg_2 (g_1 - \theta_1)(g_2 - \theta_2) p(g_1, g_2). \quad (\text{E.4})$$

Note that the spike correlation function in the LN model is symmetric in $\Delta t \rightarrow -\Delta t$ despite the different offsets for the two neurons.

In the special case where $\theta_1 = \theta_2 = 0$, the spike (auto-)correlation function can be written in a relatively simple form:

$$c(\Delta t) = \frac{1}{2\pi} \sqrt{w^2(0) - w^2(\Delta t)} + \frac{w(\Delta t)}{4} + \frac{|w(\Delta t)|}{2\pi} \arctan \frac{|w(\Delta t)|}{\sqrt{w^2(0) - w^2(\Delta t)}}. \quad (\text{E.5})$$

For any two thresholds, the behavior for large $|\Delta t|$ can be found from the expansion of $p(g_1; g_2)$, from which we obtain

$$c(\Delta t) \simeq r_{0,1} r_{0,2} + \frac{\phi_0^2}{4} w(\Delta t) \operatorname{erfc}\left(\frac{\theta_1}{\sqrt{2w(0)}}\right) \operatorname{erfc}\left(\frac{\theta_2}{\sqrt{2w(0)}}\right), \quad (\text{E.6})$$

where

$$r_{0,i} = \sqrt{\frac{w(0)}{2\pi}} \exp\left(-\frac{\theta_i^2}{2w(0)}\right) - \frac{\theta_i}{2} \operatorname{erfc}\left(\frac{\theta_i}{\sqrt{2w(0)}}\right) \quad (\text{E.7})$$

are the firing rates of the two neurons and erfc is the complementary error function.

For a more direct comparison with the threshold-crossing model, it is instructive to consider a transfer function concentrated at a particular value θ : $\phi(x) = \phi_0 \delta(x - \theta)$. We then find that for large $|\Delta t|$,

$$\frac{c(\Delta t) - r_{1,0} r_{2,0}}{r_{1,0} r_{2,0}} \simeq \frac{w(\Delta t)}{w^2(0)} \theta_1 \theta_2, \quad (\text{E.8})$$

which is the same as the first term in equation B.24. The firing rate in the LN model, appearing on the left-hand side of equation E.8, is given by

$$r_{0,i} = \frac{\phi_0}{\sqrt{2\pi w(0)}} \exp\left[-\frac{\theta_i^2}{2w(0)}\right] \quad (\text{E.9})$$

Acknowledgments

We acknowledge helpful discussion with Robert Gütig and Markus Meister, and thank Uri Rokni for useful comments on the manuscript. We thank Markus Meister for sharing with us his unpublished notes on threshold-crossing processes. Y.B. acknowledges support from the Swartz Foundation. H.S. is partially supported by a grant from the ISF and from the Israeli Ministry of Defense (MAFAT).
